The best routine depends on the detailed statistics of your data, i.e.
it is often appropriate to cache the last point and search outwards.
The following takes of the order log base 2 of 200 operations, i.e., 8 *
a small factor, while your method takes on the order of 200 operations,
unless the data always lies at small values.

```
lbound= 0
ubound = 199
guess = 100
while ubound - lbound gt 1 do begin
  IF rad GT WVRADarr(guess) then $
    lbound = guess $
  else ubound = guess
  guess = (ubound + lbound) / 2L
endwhile
TempK = WVTEMParr(lbound)
```

The following should be a vectorizable version of the same idea

```
lbound = Lonarr(N_elements(rad))
ubound = lbound + 199
guess = lbound + 100
n_iterate = 9
for i=0, n_iterate-1 do begin
  ndx = where(rad GT WVRADarr(guess), count)
  if count gt 0 then lbound(ndx) = guess(ndx)
  ndx = where(rad LE WVRADarr(guess), count)
  if count gt 0 then ubound(ndx) = guess(ndx)
  guess = (ubound + lbound) / 2L
endfor

TempK = WVTEMParr(lbound)
```

Mind you I haven't checked the following for boundary conditions, in
particular it might be that n_iterate should be 8 or lbound might be off

by 1 from what you want.
