Hi All,

I have some data files with an unknown number of columns with unknown labels (as in I don't know in advance of reading each file what they will contain). I find working with IDL structures much clearer than anonymous multiple dimensional arrays, so this is my a fragment from my solution to constructing an array of a structure to hold the data:

```
tags = <strarr of the column labels>
nrows = <int derived after reading in data to temporary strarr line by line>
```

```
command = 'data_struct= {'
for i=0,n_elements(keys)-1 do command += ','+tags[i]+'0.'
command += '}'
execute(command)
data = replicate(data_struct,nrows)
```

Then I fill data using by looping over rows and columns using the data.
(j) structure interface.

This feels like an awful hack, and has the limitation that it can only be run once a session as I can't work out how to specify the name of the structure (since replicate can't be convinced to interpret a string as the name of a structure).

I wrote a Hash implementation that I use for this kind of thing myself (we use IDL 7.1 around these here parts) but for code that my colleagues will use I'm trying to make the outputs as simple as possible as custom objects are not used much and in any case the syntax is clumsy.

Any ideas?
